

An Inverted L Antenna with a Parasitic Structure for RFID

S. R. Meneses González¹, L. Montes Peralta¹

Abstract— an inverted L antenna altered by a parasitic resonant structure is designed for RFID tag. In order to determine the performance of varying design parameters on impedance and resonance frequency, HFSS simulation software and experimental tests are carried out. This way, the focus of this work is RFID tag antenna design based on the structure above mentioned.

Keywords— impedance antenna, inverted L antenna, RFID tag, resonance frequency, S_{11} parameter.

Resumen— Una antena del tipo L invertida alterada por una estructura parásita resonante es diseñada para su aplicación en la etiqueta RFID. Con objeto de determinar el comportamiento de los parámetros de diseño, esto es, impedancia y frecuencia de resonancia, se ha utilizado el software de simulación HFSS y pruebas experimentales se han llevado a cabo. Así entonces, el objetivo de este trabajo es el diseño de una antena para etiqueta RFID basada en la estructura mencionada.

Palabras Clave— impedancia de antena, antena L invertida, Etiqueta RFID, frecuencia de resonancia, parámetro S_{11} .

I. INTRODUCTION

Radio Frequency Identification is now generating significant interest in the marketplace because of its robust application capabilities. RFID enables healthcare facilities improve overall safety and operational efficiency because it operates without line-of-sight while providing read/write capabilities for dynamic item tracking, used to identify objects or people with no physical contact or visual supervision, for instance: consumer packaged goods, animal identification, waste management systems, hospitals, libraries, vehicular identification and even humans tagged with RFID chips [1].

RFID applications consist of a wireless communication link between a remote transponder (antenna and integrated circuit), known as the tag, containing the information into the memory block, and an interrogator or reader, which emits radio waves and collects part of them reflected

back by the RFID tag.

Various types of antennas for RFID tag have been proposed and the challenge trends to design a RFID tag antenna which dimensions must be enough small size for be assembled with the chip, at the same time satisfy gain, resonance frequency, impedance requirements, in order to match to the passive RFID integrated circuit (IC) and achieve maximum efficiency, as well as bandwidth requirements (low KHz) and low cost [2].

The chips are made to cover three UHF RFID frequency ranges for different regions: Europe (866.5 MHz), North America (915 MHz), Asia (953 MHz), and there are two kinds of the tags, the active tags which are powered by batteries radiating RF electromagnetic energy permanently, for the reader localization, and passive tags powered by the reader's field, the received electromagnetic signal charges an internal charge storing capacitor in the tag chip, which in turn, acts as a power source and supplies the power to the chip energy answering the reader back [3].

In some applications the RFID tag operates as a fixed receiver, firmly attached to the objects to be identified which are generally permanent in the same position, in this case it is enough to use an antenna with not high gain, low radiofrequency, for instance 13.56 MHz, in this case HF tags use inductive coupling in the near-field region as the wavelength is much longer, the distance between the reader and the tag is short, with not obstacles, that is, line of sight, and the readout can be taken successfully.

But at other RFID applications, for instance vehicular identification, livestock identification, etc., the RFID tag continuously is moving, thus, the antenna polarization is changing constantly, the distance between the reader and the tag is very significant, from what other parameters must be considered, as far field, antenna gain, radiation pattern, operation frequency due to it is shorter wavelength at UHF band [4].

This way, the focus of this work is the tag antenna design for RFID UHF Band, 915 MHz, based on L inverted antenna altered with a parasitic resonant structure which complies with small size, acceptable gain and radiation pattern.

II. RFID TAG ANTENNA DESIGN

A. Design Foundations

The antenna in question consists of a monopole antenna folded in a specific point in order to create two sections, similar to inverted L letter, the horizontal section serves as load to the vertical section, forcing a trapezoidal distribution current along the cooper strip improving the antenna radiation characteristics [5]. The inverted L antenna geometry is shown in Figure 1. Evidently the single antenna as shown in Figure 1 is a limited antenna, but in order to take control on resonance frequency adjustment, and improve gain and radiation characteristic, it is possible when it is inserted a parasitic element, a micro strip rectangular ring, between the horizontal section and ground plane, one half of it on front side of the dielectric, that is, PCB (FR4) and the other half on the back side, making a gap between them, with no contact with the inverted L antenna as shown in Figure 2.

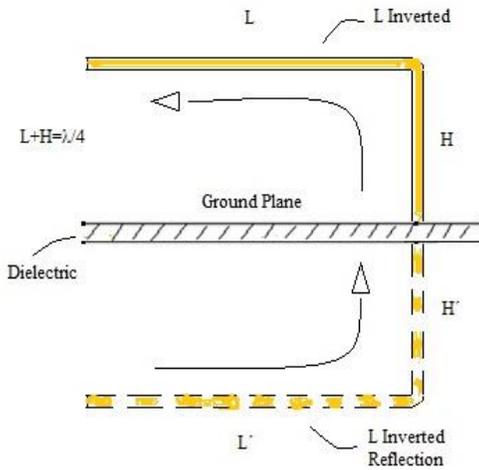

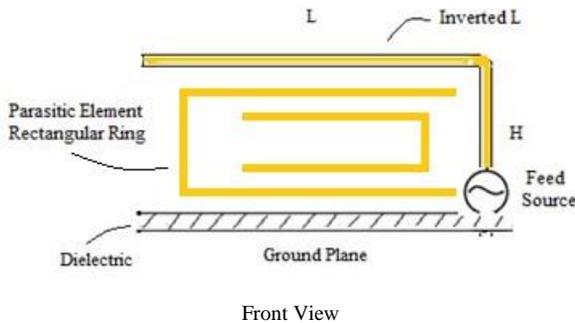

Figure 1. Inverted L antenna geometry.

Front View

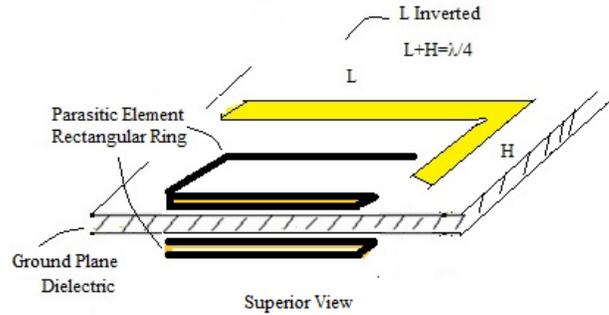

Figure 2. Inverted L antenna with parasitic resonant structure, front and superior view.

The equivalent circuit of this kind of antenna is shown in Figure 3, it is composed by resistance, inductance and capacitance of the inverted L element, in the same way, resistance, inductance and capacitance of resonant rectangles, as well as, capacitance between rectangles, and mutual inductance and mutual capacitance between the inverted L element and the parasitic element resonant structure. Mutual coupling has been proven to be a useful mechanism to improve the bandwidth to achieve the frequency bands for mobile antennas when and extra antenna element is coupled to the driven element [8].

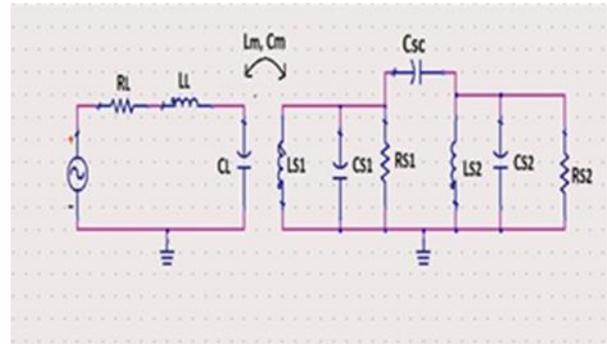

Figure 3. Equivalent circuit.

The resonance frequency is divided into the high-frequency side and low frequency side by adding the ring structure. The L antenna and the rectangular ring on the front side define the low frequency and the back side the high frequency. Each frequency can be adjusted changing the length of the rings. This way, the resonance frequencies are given by [9]:

$$f_1 = \frac{1}{2\pi \sqrt{(L_s \pm L_m)(C_s + C_m)}} \quad (1)$$

$$f_2 = \frac{1}{2\pi\sqrt{(L_s - L_m)(C_s - C_m)}} \quad (2)$$

For our objective it is necessary just one resonance frequency, 915 MHz, the other resonance frequency can be adjusted to European RFID Technology 866.5 MHz, and/or Asian RFID Technology, 953 MHz.

B. Simulation

Software HFSS [10] has been used to simulate the designed antenna. The structure and dimensions of designed antenna are shown in Figure 4. Although the inverted L element length should be designed equal to $\lambda/4$ [11], in order to achieve a resonant frequency equal to 915 MHz, it was necessary add a corrective circuit, shown in Figure 5.

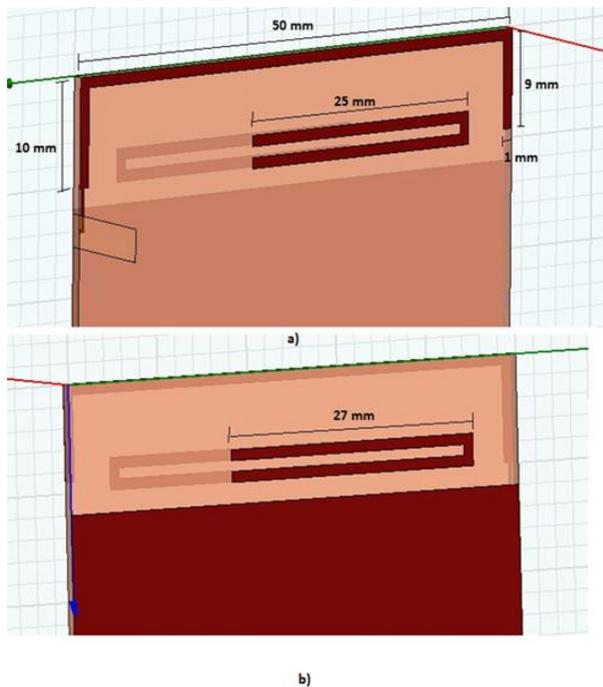

Figure 4. Inverted L antenna with rectangle rings structure (Simulation). a). Front Face. b). Rear Face.

As a result of simulation, S_{11} parameter graphic is shown in Figure 6 which resonance frequency is 914 MHz. In the same way the Radiation Pattern graphic is shown in Figure 7, Plane E is illustrated in red color, and Plane H is in blue color, as well as, the antenna gain value in a specific direction is shown.

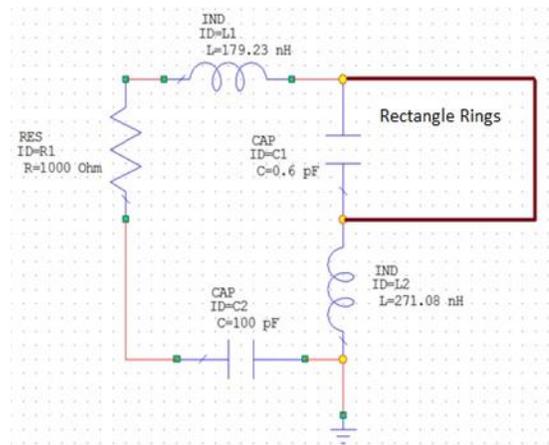

Figure 5. Corrective Circuit.

C. Implementation and measurement

Fig. 8 shows the prototype antenna, the L inverted monopole antenna and the rings are formed on the front and rear side of an FR-4 dielectric substrate ($\epsilon_r = 4.4, \tan \delta = 0.02$), the SMA connector and L antenna are mounted on the front side of the FR4 dielectric substrate [12]. The other components are mounted at the rear side of it. The dimensions and values of each one of the components are approximately equal to calculated values. The PCB ground area can be reduced in accordance with experimental results.

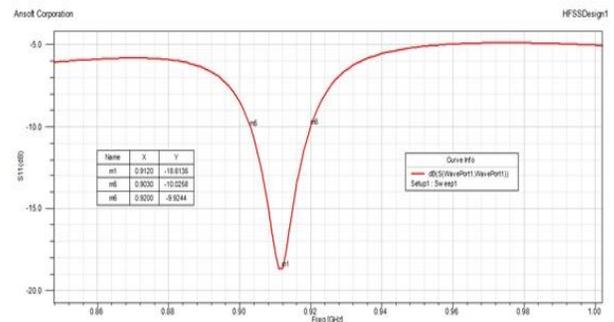

Figure 6. S11 Parameter Graphic (Simulation).

In order to measure the resonance frequency and impedance of the designed antenna, we have frequency used a Vector Network Analyzer ZVB40 calibrated in the band 500 MHz – 2 GHz, as shown in Figure 9. It is possible to observe at Magnitude vs. Frequency graphic, that, the resonance frequency is equal to 914.43 MHz, - 14.16 dB, in accordance with simulation result.

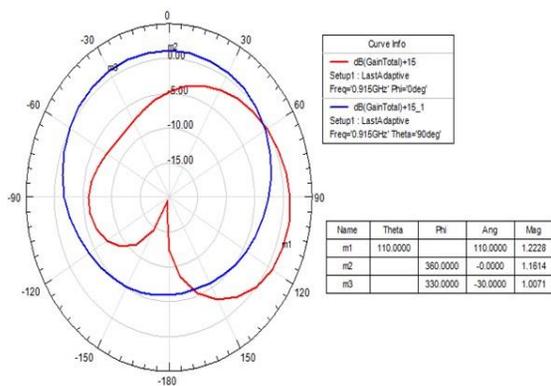

Figure. 7. Radiation Pattern (Simulation). Plane E (red color), Plane H (blue color).

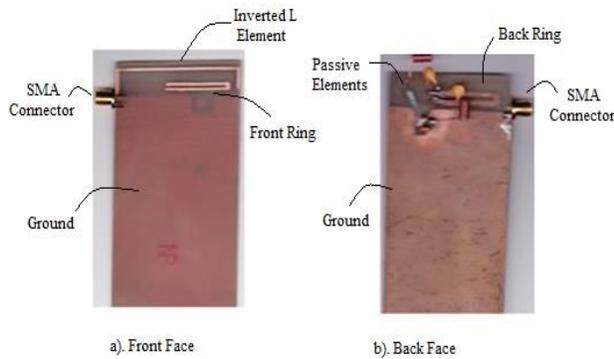

Figure. 8. Prototype Antenna.

Measured impedance value of the implemented antenna is shown in the Smith Chart in Fig. 10, equal to $69.11 - j14.404 \Omega$, 12.08 pFd , an excellent value in the real part, however, the imaginary part is capacitive, the desired value is an inductive reactance in order to cancel the capacitive part of the chip impedance [13], $Z_{chip} = 73 - j113\Omega$, and have the maximum matching. This way in accordance with experimental results, we should trade with maximum efficiency and/or resonance frequency.

On the other hand, in order to measure the radiation pattern of the antenna under test, this one was positioned into an anechoic chamber as shown in Fig. 11 to result in Plane-E and Plane-H radiation pattern shown in Fig. 12. It is possible to observe that these ones are similar with simulation results, there are nulls in specific points, however, even so due to the geometry of the achieved radiation pattern, the RFID tag can be detected by the RFID reader from any position and the feasibility of the designed antenna for this application is guaranteed.

III. CONCLUSION

Antenna design based on driven element coupled to an extra antenna element for RFID tag has been implemented

and measured, the mutual coupling has improved the radiation characteristics in order to meet the resonance frequency, radiation pattern and input impedance requirements, as well as, an acceptable antenna gain and small size, this way, the designed antenna is feasible to be applied for RFID Technology.
